Duplexing

- Allow the subscriber to send “simultaneously” information to the base station while receiving information from the base station.
  - Talk and listen simultaneously.

- Definitions:
  - **Forward channel** or **downlink (DL)** is used for communication from the infrastructure to the users/stations
  - **Reverse channel** or **uplink (UL)** is used for communication from users/stations back to the infrastructure.

- Two techniques
  1. Frequency division duplexing (FDD)
  2. Time division duplexing (TDD)

[Rappaport, 2002, Ch 9]
Frequency Division Duplexing (FDD)

- Provide *two distinct bands* of frequencies (simplex channels) for every user.
- The **forward band** provides traffic from the base station to the mobile.
- The **reverse band** provides traffic from the mobile to the base station.
- Any *duplex* channel actually consists of two *simplex* channels (a forward and reverse).
- Most commercial cellular systems are based on FDD.
FDD Examples

GSM

[Karim and Sarraf, 2002, Fig 5-1]

UMTS

[Karim and Sarraf, 2002, Fig 6-1]
**Time Division Duplexing (TDD)**

- The UL and DL data are transmitted on the **same carrier frequency** at different times. (Taking turns)
  - Use time instead of frequency to provide both forward and reverse links.
  - Each *duplex* channel has both a **forward time slot** and a **reverse time slot**.
- If the *time separation* between the forward and reverse time slot is *small*, then the transmission and reception of data *appears* simultaneous to the users at both the subscriber unit and on the base station side.
- Used in Bluetooth and Mobile WiMAX
Problems of FDD

- Each transceiver simultaneously transmits and receives radio signals
  - The signals transmitted and received can vary by more than 100 dB.
  - The signals in each direction need to occupy bands that are separated far apart (tens of MHz)
- A device called a **duplexer** is required to filter out any interference between the two bands.

[Tse and Viswanath, 2005, Ch 4, p 121]
Advantages of FDD

- TDD frames need to incorporate guard periods equal to the max round trip propagation delay to avoid interference between uplink and downlink under worst-case conditions.

- There is a time latency created by TDD due to the fact that communications is not full duplex in the truest sense.
  - This latency creates inherent sensitivities to propagation delays of individual users.
Advantages of TDD

- Duplexer is not required.
- Enable *adjustment* of the downlink/uplink ratio to efficiently support *asymmetric* DL/UL traffic.
  - With FDD, DL and UL always have fixed and generally, equal DL and UL *bandwidths*.
- Assure *channel reciprocity* for better support of link adaptation, MIMO and other closed loop advanced antenna technologies.
- Ability to implement in *nonpaired spectrum*
  - FDD requires a pair of channels
  - TDD only requires a single channel for both DL and UL providing greater flexibility for adaptation to varied global spectrum allocations.

Multiple Access Techniques

- Allow many mobile users to share simultaneously a finite amount of radio spectrum.
- For high quality communications, this must be done without severe degradation in the performance of the system.
- Important access techniques
  1. Frequency division multiple access (FDMA)
  2. Time division multiple access (TDMA)
  3. Spread spectrum multiple access (SSMA)
     - Frequency Hopped Multiple Access (FHMA)
     - Code division multiple access (CDMA)
  4. Space division multiple access (SDMA)
  5. Random access
     - ALOHA
Chapter 4
Multiple Access

4.3 FDMA and TDMA
Frequency division multiple access (FDMA)

- The *oldest* multiple access scheme for wireless communications.
- Used exclusively for multiple access in 1G down to individual resource units or physical channels.
- Assign individual channels to individual users.
  - Different carrier frequency is assigned to each user so that the resulting spectra do not overlap.
  - During the period of the call, no other user can share the same channel.
- **Band-pass filtering** (or heterodyning) enables separate demodulation of each channel.
FDMA (2)

- If an FDMA channel is not in use, then it sits idle and cannot be used by other users to increase or share capacity.
  - It is essentially a wasted resource.
- In FDD systems, the users are assigned a channel as a pair of frequencies.

[Rappaport, 2002, Ch 9, p. 449]
Time division multiple access (TDMA)

- Divide the radio spectrum into **time slots**.
- In each slot only one user is allowed to either transmit or receive.
- A channel may be thought of as a particular time slot that reoccurs every frame, where \( N \) time slots comprise a frame.
- Transmit data in a **buffer-and-burst method**
  - The transmission for any user is non-continuous.
  - Digital data and digital modulation must be used with TDMA.
  - This results in low battery consumption, since the subscriber transmitter can be turned off when not in use (which is most of the time).
- An obvious choice in the 1980s for digital mobile communications.
FDMA vs. TDMA
Tradeoffs

- TDMA transmissions are slotted
  - Require the receivers to be **synchronized** for each data burst.
  - **Guard times** are necessary to separate users. This results in larger overheads.
  - FDMA allows completely **uncoordinated transmission** in the time domain
    - No time synchronization among users is required.
- The complexity of FDMA mobile systems is lower when compared to TDMA systems, though this is changing as digital signal processing methods improve for TDMA.
- Since FDMA is a continuous transmission scheme, fewer bits are needed for **overhead** purposes (such as synchronization and framing bits) as compared to TDMA.
- FDMA needs to use costly **bandpass filters**.
  - For TDMA, no filters are required to separate individual physical channels.
Guard Band vs. Guard Time

FDMA

Guard Band

time

frequency

TDMA

Guard Time

time

User#1

User#2

User#3

User#4
Example: GSM

- GSM utilizes a combination of FDMA and TDMA
- Two-dimensional channel structure

- Each narrowband channel has bandwidth 200 kHz.
- Time is divided into slots of length $T = 577 \, \mu s$. 

[Figure 7.2, Heine, 1998]
The FDMA/TDMA structure of GSM

- In full-rate configuration, eight time slots (TSs) are mapped on every frequency.

A BS with 6 carriers, as shown here, has 48 (8 times 6) physical channels (in fullrate configuration).

[Figure 7.1, Heine, 1998]
Classifications of Medium Access Control (MAC)

- MAC Protocols
  - Scheduled Access
    - Static: TDMA, FDMA, CDMA
    - Dynamic Reservation
  - Random Access
    - Static ALOHA
    - Dynamic Tree, FCFS
